

**SUMMARY**

An investigation was undertaken to measure temperature changes during therapeutic ultrasound. Various frequencies, intensities and times were used. As a result of their work the authors feel that more research should be carried out to determine the point at which high intensities of ultrasound produce dangerous temperature increases.

**INTRODUCTION**

Controversy exists over the value of ultrasound as a healing modality. We therefore felt that a quantitative evaluation of the temperature changes induced by therapeutic ultrasound was necessary.

According to the Grotthus-Draper law, energy must be absorbed before exposure to it can effect a change. Absorption of ultrasonic energy (orderly movement of particles) results in the conversion of that energy into heat (disorderly movement of particles) (Ter Haar, 1978, Licht, 1958). Absorption by any one tissue depends on that tissue's absorption coefficient and the frequency of the ultrasound. The resultant hyperthermia causes vasodilatation, an increase in blood flow and an increase in metabolic rate. Blood flow increases significantly but decreases rapidly after termination of insonation.

The depth at which heating occurs and therefore the temperature increase in the muscle depends mainly on the intensity of ultrasound applied and the soft tissue cover in the area being treated. It has been found that 5 - 10 minutes of insonation at an intensity of 1 W/cm² is necessary to heat the muscle adequately. It is also worth noticing that the hyperthermia which results from an increase in temperature in the muscle is not as great as that occurring in the skin with a comparable increase in temperature.

In our study the temperature changes induced were measured by means of thermocouples inserted into rabbits' legs. The results obtained show some interesting trends.

**EXPERIMENTATION**

An anaesthetized rabbit was insonated to evaluate the temperature changes induced by ultrasound. These temperature changes were measured using copper-constantin thermocouples which were inserted into the rabbit's thigh at various levels. The thermocouples were placed in the medial subcutaneous tissue, in the muscle, in the femur and in the lateral subcutaneous tissue. One incision was made on the medial aspect of the thigh to allow for the insertion of the thermocouples. The leg was shaved laterally and medially over the middle third of the thigh. A fine covering of hair was left on the lateral side where the ultrasound was applied.

**OPSIOMMING**

Navorsing is gedoen om temperatuurveranderings gedurende toepassing van terapeutiese ultraklank te meet. Verskillende frekwensies, intensiteite en toepassingstye is gebruik. As gevolg van hul resultate voel die skrywers dat meer navorsing gedoen behoort te word om vas te stel waar hoë intensiteite ultraklank gevaarlike temperatuurverhogings produseer.

A Sonacel Multiphon Mark II ultrasound machine was used. This unit is capable of producing a maximum power of 15 watts and has a transducer face with an area of 5 cm². In this study frequencies of 1,5 MHz and 3 MHz were applied.

In order to prevent the core temperature of the rabbit from dropping a homeothermic blanket control was used. A rectal probe monitored the temperature. The blanket automatically switched on when the temperature dropped and switched off when the temperature had risen to normal.

The ultrasound was applied to the lateral surface of the thigh by means of a stroking technique. A section approximately 6 cm long was covered in 10 seconds. At all times the surface of the ultrasound head was held parallel to the thigh. Aquasonic gel was used as a coupling medium. The emf induced in the thermocouples was recorded by a digital voltmeter. These recordings could then be converted to actual temperatures.

Frequencies of 3,0 MHz and 1,5 MHz were applied at intensities of 0,5 W/cm², 1,5 W/cm² and 2,5 W/cm² for durations of 3, 6 and 9 minutes each. Three readings for each thermocouple were recorded on the digital voltmeter and an average of the three was taken. The ultrasound machine was switched on and the rate of cooling was measured after 30, 60, 90, 120, 150, 180, 210, 240 and 270 seconds.

Separate control trials were run. The procedure in each case was identical to that described above but with the ultrasound machine switched off.

During experimentation two important observations were made:

- Although the volume of coupling medium was kept constant during the application of ultrasound it spread out to form a thin film between the treatment head and the surface being insonated.
- The rectal temperature remained constant.

**DISCUSSION OF THE RESULTS**

The graphical representation of our results showed several interesting features (Figure 1A & 1B).

The greatest change in temperature (Δ T) consistently occurred in the lateral subcutaneous tissue. This is accounted for by the fact that the skin had a higher absorption coefficient and was closest to the ultrasound head. It is important to note that the Δ T in this region was as high as 14°C and in one case the actual temperature was 49,57°C (Figure 1A). Clearly had the rabbit not been anaesthetized, severe pain would have been felt since temperatures over 45°C damage living tissue. Although blood flow per unit volume is higher in humans than in rabbits, this high increase in tempe-

Received 22 December 1980.
A temperature increase always occurred in the muscle during insonation, and, as in the case of the subcutaneous tissue, $\Delta T$ increased as intensity and exposure time increased. As was expected, no concentration of heat was found in the muscle because muscle has a low absorption coefficient and a good blood flow.

An interesting phenomenon was the heat concentration which occurred in the bone. This was due to the high absorption coefficient of the bone and its low specific heat. Concentration in the bone would be seen when the energy input was great enough to heat the bone or when blood flow changes did not mask this concentration.

An unexpected rise in $\Delta T$ occurred in the medial subcutaneous tissue. Reflection of the ultrasound probably occurred at the air/tissue interface. This made more energy available for absorption, hence the higher $\Delta T$.

From the results it was evident that the highest $\Delta T$ recorded at 3 MHz occurred during the 6 minute applications. In all the thermocouples a drop in $\Delta T$ was produced during the 9 minute applications (Figure 1A and 1B). The only reasonable explanation for this seems to be that the temperature changes induced after 6 minutes stimulated an increase in blood flow, which then had a cooling effect on the tissues during longer applications. However, when using 1.5 MHz the phenomenon was not noted in any of the thermocouples, i.e. all 9 minute applications produced the greatest $\Delta T$ (Figure 1A and 1B).

From this we can infer that blood flow changes occur more rapidly with 3 MHz than 1.5 MHz. The shorter the wavelength the greater the energy of the wave and the greater its capacity to interact with matter.

Absorption of ultrasound results in local hyperthermia and when this hyperthermia reaches temperatures of 40 - 45°C, hyperaemia results. Temperatures over 45°C damage living tissue (Dysan and Suckling, 1978). Although temperature changes alter the local blood flow, these changes are not consistent since they are occurring in a dynamic system. Blood flow changes do, however, seem to depend on the applied intensity of ultrasound and its frequency dependent interaction with tissue.

Absorption of ultrasound in a specific tissue depends on the absorption coefficient. The absorption coefficient increases from fat tissue to muscle to skin and is highest in bone (Hahn, 1978). The behaviour of the heat produced depends on the thermal conductivity ($k$), thermal capacity ($c$) and density ($p$) (Lipkin and Hardy, 1954). However, when dealing with living tissue, heating
causes vasodilation which modifies the kpc value for each heating pattern as would be expected in a similar system, without blood flow.

Temperature increases stimulate an increase in blood flow and this has a cooling effect on the tissue (Stoll, 1960). It was observed that the lateral subcutaneous tissue cooled down most rapidly, followed by the muscle and medial subcutaneous tissue, bone having the lowest cooling rate. In those cases where blood flow changes appear to have been minimal, cooling occurred more rapidly after the 1.5 MHz application than the 3 MHz applications. However, once blood flow changes had been induced, this pattern changed. The cooling rate was variable, probably due to inconsistencies in blood flow changes.

CONCLUSION

The results of the trials conducted led us to conclude that an increase in temperature can be induced with continuous ultrasound at therapeutic frequencies, intensities and times. The amount of heat produced at different depths changed with intensity and time.

We feel that this study highlights the need for further research to determine the point at which high intensities produce dangerous temperature increases.

MEDICAL OFFICERS' ATTITUDES TOWARDS PHYSIOTHERAPY

SUMMARY

A simple questionnaire was distributed amongst the Medical Officers of the Cape's Day Hospitals Organisation to ascertain their knowledge of and attitudes towards physiotherapy. The results are analysed and discussed.

In August 1978 the Day Hospitals Organisation's Physiotherapy Department decided to conduct a survey amongst their Medical Officers to assess their knowledge of and attitudes towards physiotherapy in general and their attitudes towards physiotherapy within the Day Hospitals Organisation.

The Day Hospitals Organisation consists of seventeen small community hospitals throughout the Cape Peninsula. Well-equipped physiotherapy departments of varying sizes are found in nine hospitals and treat a wide variety of patients with acute and chronic conditions on an out-patient basis.

Medical Officers are frequently required to rotate between the different Day Hospitals. It was noticed that this often radically affected the referral rate to, and therefore the work-load in, the Physiotherapy Departments. This created obvious staffing problems. A department staffed by one full-time physiotherapist could change rapidly to need two full-timers or conversely to be run on a part-time basis, depending on which Medical Officers moved and where they moved.

We decided to conduct a simple survey by drawing up a short questionnaire which they would be likely to complete. We tried not to be too intimidating and in an attempt to elicit honest answers they could remain anonymous if they wished.

The questionnaires were distributed to all the Day Hospitals, to seventy Medical Officers in all, in August 1978.

CONTENTS OF SURVEY AND ANALYSIS OF RESULTS

Of 70 questionnaires distributed 48 were returned completed. Two were returned uncompleted by Medical Officers working in hospitals without Physiotherapy Departments who felt the survey did not apply to them.

The following questions were asked. Each question has an analysis of how they were answered with our comments. (Figures in brackets indicate the actual number of Medical Officers who answered.)

Question 1

What conditions do you refer for physiotherapy as part of their treatment?
(a) Respiratory conditions ... ... 96% (46)
(b) Arthritic conditions ... ... 68% (33)
